Abstract

We study the transport of a slurry of heavier than liquid circular particles in a plane pressure driven flow in a direct simulation. The flow is calculated in a periodic domain containing 300 circular particles. The study leads to the concept of fluidization by lift in which all the particles are suspended by lift forces against gravity perpendicular to the flow. The study is framed as an initial value problem in which a closely packed cubic array of particles resting on the bottom of the channel are lifted into suspension. All the details of the flow are resolved numerically without model assumptions. The fluidization of circular particles first involves bed inflation in which liquid is driven into the bed by high pressure at the front and low pressure at the back of each circle in the top row. This kind of bed inflation occurs even at very low Reynolds numbers but it takes more time for the bed to inflate as the Reynolds number is reduced. It appears that the bed will not inflate if the shear Reynolds number is below the critical value for single particle lift-off. The flows with a single particle are completely determined by a shear Reynolds number and a gravity parameter when the density ratio and aspect ratio parameters are specified. In the multi particle case the volume fraction and distribution also matters. The transition to a fully fluidized slurry by waves is discussed.

An analytical model of the steady motion of a single particle dragged forward in a Poiseuille flow is derived and compared with a simulation. The undisturbed fluid velocity is always larger than the particle velocity producing a fluid hold-up. The effect of the hold-up in the many particle case is to greatly reduce the velocity of the mixture which may be described by a two-fluid model in which the solid laden mixture is regarded as a second fluid with effective properties.

1 Introduction

The problem of transport of particles by fluids in horizontal conduits and pipes is of considerable scientific and industrial importance and is the focus of this paper. This problem arises in the transport of coal-water slurries, in the removal of drill cuttings in drilling of horizontal oil wells and in proppant transport in hydraulically fractured rock in oil and gas bearing reservoirs, to name a few. The central unsolved fluid dynamics problem arising in these applications is the
problem of fluidization by lift. The problem of fluidization by lift can be well framed in the problem of hydraulic fracturing.

Hydraulic fracturing is a process often used to increase the productivity of a hydrocarbon well. A slurry of sand in a highly viscous, sometimes elastic, fluid is pumped into the well to be stimulated at sufficient pressure to exceed the horizontal stresses in the rock at reservoir depth. This opens a vertical fracture, some hundreds of feet long, tens of feet high, and perhaps an inch in width, penetrating from the well bore far into the pay zone. When the pumping pressure is removed, the sand acts to prop the fracture open. Productivity is enhanced because the sand-filled fracture offers a higher-conductivity path for fluids to enter the well than through the bulk reservoir rock, and because the area of contact for flow out from the productive formation is increased. It follows that a successful stimulation job requires that there be a continuous sand-filled path from great distances in the reservoir to the well, and that the sand is placed within productive, rather than non-productive, formations.

In a slot problem a particle laden (say 20% solids) fluid is driven by a pressure gradient and the particles settle to the bottom as they are dragged forward. Sand deposits on the bottom of the slot; a mound of sand develops and grows until the gap between the top of the slot and the mound of sand reaches an equilibrium value; this value is associated with a critical velocity. The velocity in the gap between the mound and the top of the slot increases as the gap above the mound decreases. For velocities below critical the mound gets higher and spreads laterally; for larger velocities sand will be washed out until the equilibrium height and velocity are reestablished (see figure 1). The physical processes mentioned here are settling and washout. Washout could be by sliding and slipping; however, a more efficient transport mechanism is by advection after suspension which we studied by direct simulation.

In fluidized beds and sedimentation columns in which particles are in a balance of buoyant weight and drag, the cooperative effects of other nearby particles enter strongly into the dynamics. These effects are described by theories of hindered motion. There is a very definite relation between the fluidization by drag of one single isolated particle and the fluidization of a particle in a swarm of other particles; for example, the Richardson-Zaki correlation [1954]. Analogous ideas must come into play in problems of slurries which are fluidized by lift rather than by drag: hindered motion effects involving the effective viscosity and the effective density of a suspension and other cooperative effects surely enter here but are not well understood.

Figure 1. Sand transport in a fractured reservoir (after Kern, Perkins and Wyant [1959]).
The problem of lift on a single particle has been treated by many authors in the low Reynolds number limit. Even in the much better understood subject of drag on a single particle, say a drag on a sphere, there are no first principle formulas and empirical relations must be used. The problem of lift on a single circular particle in Poiseuille flow at finite Reynolds numbers has been studied in direct numerical simulation by N. Patankar, Huang, Ko and Joseph [2000]; this paper has a discussion of previous work which will not be repeated here.

The aforementioned study of N. Patankar et al. is based on an ALE method using body-fitted unstructured finite element grids very closely related to the numerical method introduced by Choi [2000] and used here. A Chorin [1968] type fractional step scheme for particulate flows is introduced in the approach by Choi [2000].

Using the ALE particle mover, N. Patankar et al. did lift-off and slip-velocity fluidization studies in Newtonian and viscoelastic fluids. A heavier than liquid particle is resting on the bottom of a channel in the presence of a shear (Poiseuille) flow. At a certain critical speed, depending on the weight and diameter of the particle, the fluid properties, and the aspect ratio of the channel, the particle rises from the wall to an equilibrium height at which the buoyant weight just balances the upward thrust of fluid forces. The values of the particle velocity, the angular velocity of the particle, the slip velocity and the angular slip velocity at equilibrium together with the values of the relevant dimensionless parameters were tabulated.

In section 3 we shall do single particle lift-to-equilibrium studies at larger Reynolds numbers than N. Patankar et al. [2000] had done previously; the rise and other equilibrium properties are not smooth functions of the prescribed pressure gradient; we find instability and hysteresis which N. Patankar et al. have identified as a double turning point solutions. The existence of multiple steady solutions for single particle lifting may have important implications for slurries. Certainly such considerations are not found in models of solid-liquid flow and it is necessary to visit this question in the future.

In section 4 we carry out studies of fluidization by lift of 300 particles in the same plane Poiseuille flow used to study the lift to equilibrium of a single particle. The computation is carried out in a long periodic domain in which the volume fraction of solid circles ranges roughly between 78 % and 31%. The study is framed as an initial value problem in which a closely spaced cubic array of particles resting on the bottom of the channel are lifted into suspension.

The following picture emerges from this study. At early times the top of the array is only slightly disturbed; since the cubic crystal array is not tightly packed the top layers move forward relative to the bottom. The lifting of particles out of suspension is accomplished by a pressure mechanism clearly revealed by the simulation; liquid is driven into the bed by high pressure at the front and low pressure at the back of each circle in the top row. The particles are dislodged by this pressure mechanism. At higher Reynolds numbers single particles are thrown out of the bed in a manner resembling saltation. Typically isolated particles will fall back into the bed because the drag on an isolated particle is less than when it is among many. The permanent lifting of more particles of the bed takes shape in the formation of waves, which resemble water waves. The wave amplitude grows as the pressure gradient and flow speed increase; particles are levitated out of the bed and the levitated particles form a fluidized suspension over a basically fixed bed. This can be described as bed erosion. It is possible to erode the whole bed and fluidize
all of the particles by lift if the pressure gradient is high enough and the bed depth small enough. The wave amplitude decreases when the particles are fully fluidized.

The evolution to full fluidization is associated with a transition from a basically vertical stratification of dynamic pressure to a basically horizontal stratification of dynamic pressure. The final state of full fluidization is not steady. Internal pressure waves which propagate horizontally are associated with the propagation of particle depleted regions which could be described as an internal wave of the volume fraction.

A single heavier than liquid particle will not lift off at low pressure gradients; the particle slides and rolls on the wall; lift-off to equilibrium occurs at critical values. In the fluidized suspension we can track the evolution of the rise of the mass center of the particles. The final state of full fluidization can be determined as the leveling off of the rise of the mass center curve. The mass center did not rise even after a long computation when the pressure gradient was below the one critical for the rise of a single particle.

2 Equations of motion and scaling parameters

We use the same scales and equations as Patankar et al [2000]; (length, time, velocity, stress) = \((d, \gamma_w^{-1}, \gamma_w d, \eta \gamma_w)\) and find that the governing dimensionless equations for slurry flow of 300 circular particles can be written as

\[
\begin{align*}
R \left[ \frac{\partial u}{\partial t} + u \cdot \nabla u \right] &= -\nabla p + \frac{2d}{W} e_x + \nabla^2 u \quad \text{fluid} \\
\frac{\rho_p}{\rho_f} R \frac{dU}{dt} &= -Ge_y + \frac{2d}{W} e_x + \frac{2}{\pi} \int_0^{2\pi} \sigma d\theta \\
\frac{\rho_p}{\rho_f} R \frac{d\Omega}{dt} &= \frac{16d}{\pi} \int_0^{2\pi} e_r \cdot \sigma d\theta
\end{align*}
\]

where \(e_r\) is the radial unit vector from the center of the circle; \(\sigma = -pe_r + 2D[y]e_r\) is the stress vector,

\[
\begin{align*}
R &= \rho_f \gamma_w d^2 / \eta \quad \text{shear Reynolds number} \\
G &= \frac{\rho_p - \rho_f}{\eta \gamma_w} gd \quad \text{gravity parameter.}
\end{align*}
\]

Instead of \(R\) and \(G\) we may use the product

\[
R_G = RG = \frac{U_s d \rho_f}{\eta g U_s} = \frac{d^2 (\rho_p - \rho_f) g}{\eta}
\]

and ratio
The sedimentation Reynolds number $R_G$ does not depend on $\gamma_w$, and the generalized Froude number $R/G$ does not depend on the viscosity $\eta$.

Adherence boundary conditions are prescribed also at the boundary of each circle

$$u = U + \Omega \wedge e, d$$ (2.6)

When, as in a slurry, there are many particles the number $N$ and places of $N$ boundaries enter into the problem description. In the present case, 300 is the number and the places of these 300 particles evolve as part of the solution. We have similarity then for all evolution problems for which $N, d/W, \rho_p/\rho_f, R, G$ are identical. In fact, the density ratio $\rho_p/\rho_f$ enters only in (2.2) as the coefficient of the acceleration terms, hence does not enter for steady flow. Though steady flows of a single particle do occur and were studied by Patankar et al [2000], steady flow of many particles do not appear to occur in the multiple particle case after lift off; it is possible that the accelerations are small, however after the bed has fully expanded.

3 Problem formulation

The problem to be considered is the levitation of particles of diameter $d$ in a plane Poiseuille flow in a horizontal channel of width $W$ as shown in figure 2.

![Figure 2. Levitation of heavier than liquid particle in a plane Poiseuille flow. The disturbed flow is periodic with period $L$.](image)
The undisturbed Poiseuille flow is given by

\[ U(y) = 4U_m \frac{y}{W} \left(1 - \frac{y}{W}\right) \]

\[ U_m = U \left(\frac{W}{2}\right) = \frac{W^2 \bar{p}}{8\eta}, \]

\[ \gamma = \frac{du}{dy}, \]

\[ \gamma_w = \frac{4U_m}{W} = \frac{W \bar{p}}{2\eta} \]

(3.1)

The presence of particles disturbs the Poiseuille flow. It is assumed that the disturbance flow, satisfying equations (2.10) is periodic with period \( L \). This periodicity is strictly enforced in the computation by the construction of a periodic mesh. The solution of the disturbance flow depends on \( L \), but only weakly for large \( L \). We used \( L = 22d \) for single particle, \( L = 63d \) for 300 particles.

All the calculations were carried out in dimensional variables using CGS units. The height of the channel is \( W = 12d \) and \( d = 1 \) cm. The particle density is \( \rho_p = 1.01 \rho_f \) and the fluid density \( \rho_f = 1 \) gm/cc. We did calculations for three different viscosities \( \eta = 1, 0.2 \) and \( 0.01 \) poise, from light oil to water. For each \( \eta \), the calculations were carried out for different pressure gradient \( \bar{p} \) in dynes/cm².

The results of calculations in dimensional variables may be generalized by post processing. In the present case \( \rho_p/\rho_f, d/W, d/L \) and the number of particles in a cell are fixed and flows are completely determined by the shear Reynolds number \( R \) and gravity number \( G \) given by (2.11).

### 4 Fluidization of 300 circular particles

Here we study the problem of lift of 300 solid circles in plane Poiseuille flow (figure 2) when \( \rho_p = 1.01 \rho_f \), \( \rho_f = 1 \) gm/cc, \( W = 12d, d = 1 \) cm for viscosities \( \eta = 1, 0.2 \) and \( 0.01 \) poise (from light oil to water). The calculations is carried out in a periodic domain \( L = 63d \) which is long enough to contain four or more of the waves of pressure which characterize fully fluidized beds of 300 particles. Initially the circles are arranged in a cubic crystal array in which the particles do not touch; they are separated by 0.05 cm when \( \eta = 1 \) and \( \eta = 0.2 \) poise, and by 0.1 cm when \( \eta = 0.01 \) poise. The height of the array is 5.25 cm and 5.35 cm.

We recall that the results of calculations may be generalized by computing the values of the the shear Reynolds number \( R = \gamma_w d^2 / \nu \) and the gravity number \( G = d \left( \rho_p - \rho_f \right) g / \gamma_w \eta \) defined in (2.11). The value \( R_G = RG = \rho_f d^3 \left( \rho_p - \rho_f \right) g / \eta^2 = 9.81/\eta^2 \) is independent of \( \gamma_w \). The running index in our calculation is the pressure gradient \( \bar{p} \); given \( \eta \) this determines \( R = \rho d^2 W \bar{p} / 2\eta^2 = 6\bar{p} / \eta^2 \).
Case 1: $\eta = 1$ poise, $R_G = 9.81$

Figure 6 shows the height of the center of gravity of the 300 particles as a function of $R = 6\overline{p}$. We say that the bed height has attained its final fully fluidized value when the rise curve levels off. Average values of the bed height $\overline{H}$, the average velocity $\overline{U}$ cm/sec and angular velocity $\overline{\Omega}$ sec$^{-1}$ at full inflation are given in Table 1. The time taken for the center of gravity to reach its fully fluidized value increases as the Reynolds number $R$ decreases. Figure 7, 8, 9 and 10 show snapshots of the evolution of the bed to full fluidization at values of $R$, $G$, given in the caption to figure 6.

Animations for these snapshots can be found at our URL http://www.aem.umn.edu/Solid-Liquid_Flows. The snapshots are decorated by shades of gray coded to reveal the distribution of dynamic pressure ($\overline{p}$ in equation (2.6)); dark means low pressure. Figures 11 and 12 give graphs of the pressure at different cross-sections of the channel for $R = 120$ at an early time $t = 0.9$ sec and when the suspension is fully fluidized at $t = 27$ sec. At early times the pressure is stratified vertically, but not horizontally; at the later time the pressure is stratified horizontally and not vertically.

![Graph of rise curves for the center of gravity of 300 circular particles fluidized by lift (fluid viscosity = 1.0 poise, $G = 9.81/R$). The time scale for the slow rise at $\overline{p} = 0.9$ dynes/cm$^2$ has been compressed by 2; the real time corresponding say, to 50.01 is 100.02 sec. The bed is said to be fully fluidized when the rise curves level off. The time to full fluidization is longer when the Reynolds number is smaller.](image-url)

Fluidization of 300 circular particles

Figure 7. Snapshots of the fluidization of lift of 300 circular particles $\rho_p = 1.01 \text{ g/cm}^3$ when $\eta = 1$ poise ($R = 5.4$, $G = 1.82$). The flow is from left to right. The gray scale gives the pressure intensity and dark is for low pressure. At early times particles are wedged out of the top layer by high pressure at the front and low pressure at the back of each and every circle in the top row. The vertical stratification of pressure at early times develops into a "periodic" horizontal stratification, a propagating pressure wave. The final inflated bed has eroded, rather tightly packed at the bottom with fluidized particles at the top.
Fluidization of 300 circular particles

Figure 8. Fluidization of 300 particles (R = 16.2, G = 0.61). The conditions are the same as in figure 7 except that the lift forces are greater leading to a more complete and faster fluidization.
Fluidization of 300 circular particles

\[ \frac{R}{G} = 60, \quad G = 0.16 \]

The conditions are as in figure 7. The ratio \( \frac{R}{G} = \frac{\gamma_u^2 d}{(g \Delta \rho / \rho)} \) measures the ratio of lift to buoyant weight. Here the ratio is very large leading to fast and complete fluidization; the entire bed has eroded.
Figure 10. Fluidization of 300 particles ($R = 120, G = 0.08$). The conditions are the same as in figure 7 and figure 9 but the ratio of lift to buoyant weight is greater and the fluidization is faster and the particle mass center rises higher than in the previous figures.
In figures 11 and 12 we plotted the distribution of pressures at an early and late time when $R = 120, G = 0.08$. The figures show that the vertical stratification of pressure at an early time evolves to waves of pressure which are associated with propagating number density or voidage waves.

Figure 11. Distribution of dynamic pressure $p$ and streamwise velocity $u$ at an early time ($t = 0.9$ sec) when $R = 120, G = 0.08$ (cf. Figure 10) at different cross sections of the channel. The dynamic pressure is stratified vertically but not horizontally. The rows of particles slide relative to one another moving like rigid bands separated by liquid.
Figure 12. Distribution of dynamic pressure $p$ and streamwise velocity $u$ after full fluidization ($t = 27$ sec) when $R = 120$, $G= 0.08$. The pressure $p$ is stratified horizontally and not vertically; pressure pulses propagate horizontally.

- **Case 2: $\eta= 0.2$ poise, $R_G = 245$**

Figure 13 shows the height of the center of the gravity of the 300 particles as a function of $R = 6\bar{p}/\eta^2$. The interpretation of figure 13 is basically the same as figure 6. Average values of the bed height $\bar{H}$ cm, velocity $\bar{U}$ cm/sec, and angular velocity $\bar{\Omega}$ sec$^{-1}$ at full fluidization are given in table 2. Snapshots of the evolution to full fluidization are shown in figures 14 and 15.
Fluidization of 300 circular particles

Table 2: Data for the forward motion of a fluidized suspension of 300 particles after the bed has fully inflated and the average height $\bar{H}$ of all particles has stopped increasing ($\eta = 0.2$). $\bar{H} = \bar{H}_o = 2.65d$ at $t=0$. $\bar{U}$ and $\bar{\Omega}$ are the average velocity and angular velocity of the particles.

Figure 13. Rise curves for the center of gravity of 300 circular particles fluidized by lift (fluid viscosity = 0.2, $RG = 9.81/\eta^2 = 245$.) $\bar{p}$ is in dyne/cm$^2$. The bed is fully fluidized when the rise curves level off. The time to full fluidization is longer when the Reynolds number is smaller. The time to full fluidization is faster when $\eta = 0.2$ than when $\eta = 1$ (figure 6). The time is scaled down by 5 and the center of gravity of the particles will eventually rise when $(R, \bar{p}) = (45, 0.3)$.

The description in the caption of figure 7 applies also to figures 14 and 15 except that the particles are more mobile when the viscosity of the fluid is smaller. The particle laden region at $t = 25$ sec in figure 14, and $t = 1.98$ in figure 15 is separated from the particle free region by an "interface" which propagates like an interfacial wave. This interface disappears at a higher $R =$
450, figure 15 for \( t > 2.7 \) sec, because the stronger lift forces push wave crests into the top of the channel; however, the pressure and associated void fraction wave persists.

The pressure wave at \( t_0 = 4.204 \) sec for the case \((\eta = 0.2, R = 450)\) in figure 15 is analyzed in figure 16. The period of this wave is \( T = 0.56 \) sec and its wavelength is 16 cm. The pressure wave is associated with a wave of solids fraction which could also be described as the passage of internal wave crests and troughs.

Figures 17 and 18, like figures 11 and 12, show the evolution of dynamic pressure from an essentially vertical stratification at early time \((t = 0.1 \) sec\) to propagating horizontal waves in the fully developed suspension at \( t = 4.95 \) sec.
Figure 14. Fluidization of 300 particles (\(\eta = 0.2\) poise, \(R = 150\), \(G = 1.63\)). The final state of the fluidization at \(t = 25\) sec has not fully eroded. The particles that lift out of the bed can be described as saltating. A propagating "interfacial" wave is associated with the propagating pressure wave at \(t = 250\).
Fluidization of 300 circular particles

Figure 15. Fluidization of 300 particles ($\eta = 0.2$ poise, $R = 450$, $G = 0.54$). The flow is from left to right. The particles can be lifted to the top of the channel.
Figure 16. Propagation of the pressure wave centered at $t_0 = 4.204$ sec in case $\eta = 0.2$ poise, $R = 450$ shown in figure 15. The period $T$ of this wave is $T = 0.56$ sec and its wavelength is 16 cm.
Fluidization of 300 circular particles

Figure 17. Distribution of dynamic pressure $p$ and streamwise velocity $u$ at $t = 0.1$ sec when $R = 350$, $\eta = 0.2$ poise. The distribution is basically vertical. This kind of distribution is typical of the earliest times. The vertical steps show how the fluid supports rows of particles. The particles move forward together, with only a small velocity.
Fluidization of 300 circular particles

**Case 3: \( \eta = 0.01 \) poise, \( R_G = 9.81/ \eta^2 = 9.8 \times 10^4 \)**

Figure 19 gives the height of center of gravity of 300 particles in water as a function of \( R = 6 \bar{p} / \eta^2 = 6 \times 10^4 \bar{p} \). The interpretation of figure 19 is basically the same as figure 6. Snapshots of the evolution to full fluidization are shown in figures 20 and 21.

The evolution to full fluidization is accomplished by pressure waves. For low Reynolds numbers the bed expansion is small; the snapshot at \( t = 116 \) sec in figure 20 is an example of bed expansion in water at low \( R \). The bed has expanded by the development of voids and dislocations near the top of the bed; only a few particles are fluidized. The bed is not severely eroded.

Fluidization in water at high Reynolds numbers is greatly different. The fully fluidized bed shown at \( t = 0.46 \) sec in figure 21 is completely eroded. The evolution of the fluidized suspension is driven by a propagating pressure wave which is in one-to-one correspondence with the propagation of voids. At \( t = 0.27 \) sec, before the bed has fully fluidized, these voids coincide with wave troughs.

Figure 18. Distribution of dynamic pressure \( p \) and streamwise velocity \( u \) at \( t = 4.95 \) when \( R = 350, \eta = 0.2 \) poise (see figure 15). The pressure and velocity distribution can be associated with "crest" and "trough" propagating void fractions.
Figure 22 and 23 show how the dynamic pressure $p$ develops as the bed evolves to full fluidization. For this case $t = 0.1$ sec is not an early time; the periodic pressure pulses which drive particles into suspension have already developed.

Figure 24 focuses on the wave properties of the evolving fluidization of 300 particles in water when $R = 1200$. The $t = 40$ sec panel of figure 20 shows a propagating and nearly spatially periodic wave of particles. Wave forms for the dynamic pressure $p$, the vertical velocity $V$ and the horizontal velocity $U$ are shown.

![Graph of $H(t)$ over time with two markers at $(R, \bar{p})=(6 \times 10^4, 1)$ and $(R, \bar{p})=(1200, 0.02)$](image)

*Figure 19. Rise curves for the center of gravity of 300 circular particles fluidized by lift ($\eta = 0.01, \text{RG} = 9.81/\eta^2 = 9.81 \times 10^4$). $\bar{p}$ is in dyne/cm$^2$. The time scale for the fast rise at $\bar{p}=1.0$ has been expanded by 100; the real time corresponding, say, to 50 is 0.5sec. The rise to full fluidization is very rapid and at full fluidization the mass center of the particles is closer to the top than to the bottom wall. The bed inflation at $R = 1200$ is modest; at early times the position of the mass center actually decreases because the circles are more efficiently packed. (hexagonally, rather than cubically packed at $t = 27$.)*
Table 3. Data for the forward motion of a fluidized suspension of 300 particles after the bed has fully inflated and the average height $H$ of all particles has stopped increasing ($\eta = 0.01$). $H = H_0 = 2.65d$ at $t = 0$. $\bar{U}$ and $\bar{\Omega}$ are the average velocity and angular velocity of particles.

Figure 20. Fluidization of 300 particles ($\eta = 0.01$ poise, $R = 1200$, $G = 81.75$). The flow is from left to right. This is a "relatively" heavy suspension with a smaller value of $R/G$. At $t = 27$ the flow packs the...
Fluidization of 300 circular particles

initial cubic array more closely into a hexagonal array and the mean bed height drops. The final fluid condition for \( t > 116 \) is mildly inflated, more closely packed at the bottom than the top.

Figure 21. Fluidization of 300 particles in water (\( \eta = 0.01 \text{ poise}, \ R = 6 \times 10^4, \ G = 1.64 \)). This is a "relatively" light suspension with a much larger value of \( R/G \). Particles fluidize easily; the mean bed height is higher than mid-channel.
Figure 22. Distribution of dynamic pressure $p$ and streamwise velocity $u$ at $t = 0.1$ sec for the fluidization of 300 particles in water when $R = 6 \times 10^4$ (see figure 21). In this case $t = 0.1$ sec is not an early time; the propagating pressure wave has already developed, but it does not yet have a big effect on the velocity distribution.
Figure 23. Distribution of dynamic pressure $p$ and streamwise velocity $u$ at $t = 0.46$ sec (see figure 21). The pressure and velocity wave coincides with the propagation of internal waves of void fractions.
Fluidization of 300 circular particles

Figure 24. (a) Distribution of dynamic pressure $p$, (b) vertical velocity $v$ and horizontal velocity $u$ in water near the upper wall ($y = 11$ cm) at $t = 40$ when $R = 1200, G = 81.75$, see figure 20). These spatially periodic waves propagate.

- Inertial mechanism of fluidization

We studied the fluidization of 300 circular particles in a Poiseuille flow. Initially the particles are arranged in a cubic array filling nearly half the channel. The flow breaks the cubic array and inflates the bed by pumping liquid into the bed. The pressures that develop in the bed can levitate the particles. Bed inflation may be divided into two regimes; an eroded bed in which only the top rows of the bed have been inflated, and a fully fluidized bed in which all of the particles are supported by lift forces from the fluid flow. The pumping of liquid into the bed at the earliest times appears to be a universal inertial effect associated with potential flow around spheres and circles. This inertial effect produces high pressure at the front and low pressure at the back side of each circle in the top row of the array. This produces a pressure differential front to back.
creating a flow into and out the bed, which dislodges particles from the top row. Further fluidization is driven by the development of a periodic wave of pressure and number density which are clearly evident in the snapshots of the bed evolution.

Apart from aspect and density ratios, the dimensionless equations are fully specified by the values of a shear Reynolds number \( R = \dot{\gamma} wd^2 / \nu \) and a gravity number \( G = d (\rho_p - \rho_f) g / \dot{\gamma} \eta \) and the number of particles in the cell. The ratio \( R/G \) is independent of \( \eta \) and can be viewed as the ratio of lift to buoyant weight whereas the product \( RG \) is independent of \( \dot{\gamma} \) and can be regarded as the ratio of buoyant to viscous damping; you get rapid bouncing around when \( R/G \) is large and high lifts, high average height and very inflated beds when \( R/G \) is large. A summary of the average height, velocity and angular velocity of the particles in the fully inflated beds for \( \eta = 1, 0.2 \) and 0.01 poise are presented in tables 1~3.
**Model of slip velocity**

In the modeling of solid-liquid flows the slip velocity is an important but sometimes ambiguous quantity. For single particle lift studies the slip velocity is defined as the difference between the fluid velocity at the particle center when there are no particles and the particle velocity. When there are many particles other possibilities become viable. For example, in the well known drift flux model (see Wallis 1969) drift velocities are defined as the difference between the component velocities and the composite velocity. This kind of definition is useful when there is large difference in the average solid and liquid velocity. In sedimenting suspensions and in suspensions fluidized by drag these large differences arise from the back flow which is absent in suspensions fluidized by lift. For such suspensions the concept of "slip" needs analysis.

Joseph [2000] proposed a model problem for plane Poiseuille flow defined in figure 25 in which we replace the circle of diameter $d$ with a long rectangle whose short side is $d$. The rectangle is so long that we may neglect effects of the ends of the cylinder at sections near the cylinder center. The midplane of the cylinder is a distance $y_1$ from the bottom wall and

$$ y_1 > d/2, \quad W - y_1 > d/2 \quad (4.1) $$

When no particle is in the flow

$$ u = \frac{\bar{p}}{2\eta} y(W - y) \quad (4.2) $$

The long particle is moved forward by shear from the Poiseuille flow at a speed $U_p$ which we shall obtain from the particles equation of motion (4.9) for steady flow. When $0 \leq y \leq y_1 - d/2$ we find

$$ u = \frac{\bar{p}}{2\eta} y \left[ y_1 - \frac{d}{2} - y \right] + \frac{U_p y}{y_1 - d/2} \quad (4.3) $$

And when $y_1 + d/2 \leq y \leq W$ we have

$$ u = \frac{\bar{p}}{2\eta} (y - W) \left[ y_1 + \frac{d}{2} - y \right] + \frac{U_p (y - W)}{y_1 + d/2 - W} \quad (4.4) $$

For the force balance consider the long rectangle whose long side is $L$ and its short side is $d$, as in figure 25. The cylinder moves forward with steady velocity $U_p$. The cylinder is impelled forward by the pressure force $(p_1 - p_2)d$ and is resisted by a shear force from the fluid motion

$$ (\tau_{xy} \bigg|_{y_1 + d/2} - \tau_{xy} \bigg|_{y_1 - d/2}) L = \eta \left( \frac{du}{dy} \bigg|_{y_1 + d/2} - \frac{du}{dy} \bigg|_{y_1 - d/2} \right) L \quad (4.5) $$
Equating the pressure and shear forces, after dividing by \( L \) and writing \((p_1 - p_2) / L = \bar{p} \), we get

\[
\bar{p} d = \eta \frac{du}{dy} \bigg|_{y_1 - d/2} - \eta \frac{du}{dy} \bigg|_{y_1 + d/2} \quad (4.6)
\]

where

\[
\frac{du}{dy} \bigg|_{y_1 + d/2} = -\frac{\bar{p}}{2\eta} \left( y_1 + \frac{d}{2} - W \right) + \frac{U_p}{y_1 + d/2 - W} \quad (4.7)
\]

and

\[
\frac{du}{dy} \bigg|_{y_1 - d/2} = -\frac{\bar{p}}{2\eta} \left( y_1 - \frac{d}{2} \right) + \frac{U_p}{y_1 - d/2} \quad (4.8)
\]

After combining the last three equations we find that

\[
U_p = \frac{\bar{p}}{2\eta} \left( \frac{W + d}{W - d} \right) \left( y_1 - \frac{d}{2} \right) \left( W - y_1 + \frac{d}{2} \right) \quad (4.9)
\]

When \( d \rightarrow 0 \)

\[
U_p \rightarrow \frac{\bar{p}}{2\eta} y_1(W - y_1) \quad (4.10)
\]

which is the value \( U(y_1) \) of the fluid velocity given by (4.2).

We next evaluate the slip \( U(y_1) - U_p \) forming the ratio.
Fluidization of 300 circular particles

\[
\frac{U_p}{U(y_1)} = \left( \frac{W+d}{W-d} \right) \left( \frac{y_1-d/2}{y_1} \right) \left( \frac{W-y_1-d/2}{W-y_1} \right)
\] (4.11)

To show that \( \frac{U_p}{U(y_1)} \) is less than 1 when \( d>0 \), we note that

\[
(W-d)y_1(W-y_1) - (W+d)(y_1-d/2)(W-y_1-d/2)
\]

\[
= (y_1-W/2)^2 + \frac{d}{8}(W-d) > 0
\]

In our simplified model the fluid velocity is larger than the particle velocity in steady flow and the lag increases as the particle diameter increases. Small particles follow the fluid with vanishing lag.

Figure 26. Velocity profiles for three different solutions with \( W = 12 \text{ cm}, d = 1 \text{ cm}, \eta = 0.2 \text{ poise and } \bar{p} = 1.2 \text{ dynes/cm}^2 \). (a) Undisturbed Poiseuille flow (b) DNS one circular particle \( h_r = 4.18 \text{ cm} \) (see Table 1) (c) model problem corresponding to figure 25 with \( y = 4.18 \text{ cm} \). The model reduces the velocity much more because the particle is long and because it does not rotate.

The calculation just given suggests that the presence of even one particle can produce a global change of the fluid velocity. This kind of global change can be generated by circles as is shown in figures 26 and 27. The velocity profiles far upstream and downstream of the particle tend to undisturbed values. The effect of particle rotation is to diminish the effect of the particle on the fluid motion. Our long particle cannot rotate but we could express an effect of rotation by
allowing for a shear profile, less than the shear in the unperturbed fluid, in the long body as if it were a very viscous fluid. The shear in the very viscous fluid would be greater than the zero shear of the solid and less than the shear in the undisturbed flow. The difference between the shear in the undisturbed fluid and the very viscous fluid can be viewed as representing the angular slip velocity. The “no shear” solid corresponds to a circular particle for which rotation is suppressed.

Figure 27. Velocity for the steady flow of a levitated particle near the wall (R = 45, G = 5.4, η = 0.2, \( \rho \) = 0.3; see table 2.) (a) velocity vector and streamlines (b) velocity profile on the vertical line through the particle center.

The presence of more than one particle produces yet more lag globally and the best way to see the change is to compare the profile with the undisturbed flow. In figure 28 we have used tecplot to plot profiles at 6 different sections of the flow of 300 particles at \( \rho = 20 \text{ dyne/cm}^3 \), \( t = 28 \text{ sec} \) identified by vertical lines in figure 10. The open circles give the velocity at fluid points. The straight line segments pass through particles which are rotating. There is no slip velocity in such a plot; the velocity is continuous through the particle.
Fluidization of 300 circular particles

Figure 28. Fluid velocity profiles at 6 different sections of the flow of 300 particles at $p = 20 \text{ dyne/cm}^3$, $\eta = 1.0$ and when it is fully fluidized ($t = 28$).

In figure 29 we plotted the 10 average fluid velocities as a function of $y$. They are obtained by averaging fluid velocities at about 1000 points of $x$ coordinate at a fixed $y$. These averages are shown as 10 black circles. A scatter plot of particle velocities is shown and a polynomial fit to this scatter plot is given as a light solid. There does not seem to be a large difference between the average fluid velocity and the average solid velocity defined in this way, but a small positive difference between the fluid and particle velocities is vaguely evident. On the other hand, the difference between the composite fluid-solid velocity and the particle free Poiseuille flow profile is dramatic.

The data shown in figure 29 suggests that one of the main effects of particles in a fluid is to radically reduce the velocity of the composite. Each particle produces a drag on the fluid in a freely moving suspension. The effect of such a distributed drag is equivalent to some form of effective viscosity. Algorithms for the construction of such effective viscosities would find many important applications. Unfortunately the empirical forms of effective viscosity functions which work well for uniform fluidized and sedimenting suspensions work much less well for sheared suspensions.
Fluidization of 300 circular particles

Figure 29. Scatter plot of particle velocities (+) of 300 particles taken from figure 28 (η = 1 poise, \( \bar{p} = 20 \) dyne/cm\(^2\)); (a) average particle velocity for the scatter (—); (b) average fluid velocity taken from the tecplots in figure 28 at 10 values of \( y \) over 1000 points; (c) two-fluid Poiseuille flow model based on (4.14) and (4.15) using the effective viscosity \( \eta_m = 3.06 \) from (4.12) with \( \phi = 0.36 \) and (d) \( \eta_m = 4.19 \) from (4.13); (e) undisturbed Poiseuille flow. The particles “hold up” the fluid. The increased drag on the fluid due to the free particles can be modeled as an effect of an increased viscosity of the fluid-solid mixture.

For comparison, we calculated velocity profiles using a two-fluid effective viscosity theory. We suppose that the particle-laden region is an effective fluid with an effective viscosity and an effective density, though the effective density is not needed for the calculation to follow. The selection of the region occupied by the fluid-solid mixture is somewhat arbitrary. We suppose that the mixture has a uniform volume fraction under a flat interface of height \( 2\bar{H} \) where \( \bar{H} \) is the mean height. The volume fraction is obtained as \( 300\pi d^2/8\bar{H}L \) where \( d=1cm, L=63cm \). Two highly regarded expressions for the effective viscosity of a uniform suspension of spheres of volume fraction \( \phi \) are:

\[
\eta_m = \eta_f / (1 - \phi / A)^2, \quad A=0.638
\]  \hspace{1cm} (4.12)

which is due to Kataoka et al.[1978] into two dimension and

\[
\eta_m = \eta_f (1 + 2.5\phi + 10.05\phi^2 + 0.00273e^{16.6\phi})
\]  \hspace{1cm} (4.13)
which is due to Thomas [1965]. These expressions were obtained from experiments and may not apply in two dimensions. We used $A = A_{2D} = 0.8328$ which scales $A$ into two dimension in the ratio of close packed hexagonal packings in 2 and 3 dimensions $A_{2D} = \frac{0.907}{0.740} A_{3D}$. The effective theory is a two-fluid stratified Poiseuille flow satisfying the following equations

$$\bar{\rho} = \eta_f \frac{\partial^2 u_f}{\partial y^2} \quad \text{for} \quad y \geq h, \quad \bar{\rho} = \eta \frac{\partial^2 u_m}{\partial y^2} \quad \text{for} \quad y \leq h$$  \hspace{1cm} (4.14)

where $h = 2\overline{H}$ is the interface between the pure fluid and the mixture. At the boundary

$$u_f (W) = 0.0, \quad u_m (0) = 0.0 \quad \text{and the velocity and shear stress are continuous on} \quad y = h;$$

$$u_f (h) = u_m (h)$$

$$\eta_f \frac{\partial u_f}{\partial y} (h) = \eta \frac{\partial u_m}{\partial y} (h). \hspace{1cm} (4.15)$$

The comparison of the effective theory corresponding to (4.12) and (4.13) with the numerical simulation is exhibited in figure 29. The agreement between the effective theory and the simulation is far from perfect but there is agreement within a large tolerance. The effective theory however has several big defects which must be overcome before it can be used to model the slurry; first and foremost the theory requires that $h$ be specified; here from the simulation a second problem is that the effective viscosity for uniform suspension need not be a good representation of sheared suspension. It is certain the effective density of the slurry must enter into the height of the fluidized slurry in ways we don’t yet understand.

The small difference between the spatially averaged fluid and solid velocities cannot be said to be clearly evident at all positions on a cross section. It is our position that a positive slip velocity is required to support the buoyant weight of particles. In fact, we would expect that the difference between the particle weight and the composite density $\rho (\phi) = \rho_p \phi + \rho_f (1- \phi)$ is a factor in the unknown formula for the lift on a particle in a swarm of volume fraction $\phi$. In the present case $\rho_p - \overline{\rho}(\phi) = (\rho_p - \rho_f)(1- \phi) = 0.01(1- \phi)$ is very small and a large slip velocity is not required to levitate a particle. The calculation of the slip velocity ought to be defined in terms of time or ensemble averages at a fixed point, which are not readily calculated with the ALE method used here.
Figure 30. Scatter plot for the fluidization of 300 particles in water ($\eta = 0.01$ poise) shown in figure 21. In this case, particles fill the whole channel and the scatter is caused by large fluctuations. (a) The average velocity profile (—) is rather flat as would be expected from turbulent flow. The black dots ⋅ are average fluid velocities from the tecplots in figure 21. (b) Velocity profile for Poiseuille flow of a fluid with effective viscosity $\eta_m = 0.032$ given by (4.13) for $\phi = 0.31$. This does not agree with the simulation. Perhaps it would be better to create an effective "eddy viscosity" theory for this weakly turbulent flow. (c) Undisturbed Poiseuille flow without particles.

Figure 30 gives a scatter plot for the water flow in figure 21($\eta = 0.01$ poise, $R = 6 \times 10^4$, $G = 164$). The results here are what might be expected of turbulent flow and appear to represent the natural extrapolation of results given in this paper at lower Reynolds numbers. The relevant Reynolds number, based on the average particle velocity $\bar{U} = 200$ cm/sec, the effective viscosity $\eta_m = 0.032$ poise and particle diameter $d$, is about 6000, a value at which one might expect weak turbulence. Informed readers will question the validity of our computation using Choi’s [2000] split method in direct numerical simulation with no artificial viscosity or turbulence model. The natural way to test this result is to do mesh refinement. Our unstructured mesh is generated automatically from nodes on the surface of the circular particle. Our calculation converged, and converged solutions have nearly the same height history for 15 to 30 nodes on the circular particle when the time step size ($\Delta t$) used is about $10^{-5}$ (the corresponding Courant number is about 0.1); the converged solution cannot be obtained when the number of nodes is less than 12 or sometimes greater than 30. When the number of nodes is greater than 30, the calculation may stop because the mesh generator is unable to generate mesh due to the distortion of very short elements during motion. Certainly we have not established the validity of such a high Reynolds...
number computation, but the results do converge to something which appears reasonable and survives tests of mesh refinement.

5 Summary of results

1. A numerical package (H. Choi [2000]) based on a splitting method, which is an extension of the numerical package developed by Hu, Joseph and Crochet [1992] for the direct numerical simulation of solid-fluid mixtures, is used to study the fluidization by lift of 300 particles.

2. The present problem is governed by a shear Reynolds number $R$ and a gravity number $G$. The product $R_G = R G$ is a Reynolds number based on the sedimentation velocity of a sphere under gravity. This is a measure of the activity level and is small when the viscosity is large. The ratio $R/G$ is a generalized Froude number; it compares the inertial lift due to the shear to the buoyant weight and is independent of viscosity; the rise of particles is large when this number is large even though the motion may be sluggish.

3. A turning point bifurcation of a steady forward flow of a single particle was found; the height and particle velocity change strongly at such points and the solutions may exhibit hysteresis. The proof that the arrangement of stable and unstable solutions is associated with double turning points is given in the paper by N. Patankar et al. [2000]

4. The transport of a slurry of 300 particles heavier than liquid particles in a plane pressure driven flow was studied using DNS. Time histories of fluidization if the particles for three viscous fluids with viscosity $\eta = 1.0, 0.2$ and $0.01$ (water) were computed at different pressure gradients. The time history of the rise of the mean height of particles at a given pressure gradient is monitored and the rise eventually levels off when the bed is fully inflated. The time taken for full inflation decreases as the pressure gradient (or shear Reynolds number) increases. The bed does not inflate when the critical value is below the critical value for lift off of a single particle.

5. At early times, particles are wedged out of the top layer by high pressure at the front and low pressure at the back of each particle in the top row.

6. The dynamic pressure at early times basically balances the weight of the particles in the rows defining the initial cubic array. This vertical stratification evolves into a horizontally stratified propagating wave of pressure which tracks waves of volume fraction. The pressure wave is strongly involved in the lifting of particles. For low viscosity fluids like water where $R G$ is large the particle-laden region supports an “interfacial” wave corresponding to the wave of pressure. If $R/G$ is large the interface collapses since the stronger lift forces push wave crests into the top of the channel, but the pressure wave persists.

7. A simple analytic model for the free motion of a single particle of diameter $d$ in Poiseuille give rise to a formula for the particle velocity

$$\frac{U_p}{U(y_1)} = \left(\frac{W + d}{W - d}\right) \frac{y_1 - d/2}{y_1} \left(\frac{W - y_1 - d/2}{W - y_1}\right)$$
where \( y_1 \) is the distance from the channel bottom to the particle center, \( U(y_1) \) is fluid velocity at \( y_1 \) when no particle is present and \( W \) is the channel height. The slip velocity \( U(y_1) - U_p > 0 \) is positive but tends to zero with the particle diameter. The presence of particles produces a lag in the fluid velocity and the effect of such a drag can be interpreted as an effectively increased viscosity for the fluid-solid mixture.

8. DNS data can be sampled for average fluid and average solid velocities. The difference of these velocities is very small, but the difference between the composite velocity and the particle free Poiseuille flow is dramatic. We attempted to model the average flow of the slurry by a two-fluid model in which the particle laden region is treated as a fluid with an effective viscosity; for this calculation we used two different well regarded formulas for the effective viscosity with pure liquid above the mean height and effective liquid below. We would like to be able to predict the mean height from considerations involving an effective density.
